The monitoring of intestinal oxygen saturation by means of a pulse oximeter is routinely applied in human medicine during surgery of the gastrointestinal tract to evaluate the disturbance of perfusion and assess tissue viability. To some extent, this technique has been applied in veterinary medicine. The purpose of this study was to test the technique in cattle and to describe the influence of gas volume and intraluminal pressure of the displaced abomasum on oxygen saturation of the organ.

The study was performed on 35 cows suffering from left or right abomasal displacement (LDA, 20 cows; RDA (torsions $\geq 180^\circ$, 15 cows). The cows, ages 2,5 to 7 years, were a cross between the local dairy cow breed (Schwarzbuntes Milchrind) and Holstein-Friesian.

A pulse oximeter (CardiicapII-CG) was used to monitor oxygen saturation on the displaced abomasum and, as a comparison, on the rumen. The pulse oximetry probe was attached to the highest point of the gas-filled vault of the abomasum and the most caudal aspect of the dorsocaudal ruminal sack (transmission pulse oximetry). The gas pressure was measured by cannulating a needle (diameter 2,1 mm,) and a non-compressible tube connected to the electronic manometer (BMT 401). The gas volume was measured by aspirating the complete gas volume with an aspirator (GF 80) and pipelining the gas into a water-filled container to displace the water. The displaced water volume was registered as the indirect gas volume.

The oxygen saturation of the abomasal wall was lower in cows with right abomasal volvulus (79,4 %) than in cows with LDA (83,8 %). In comparison to the abomasum, the oxygen saturation of the dorsal rumen was 89,1 % in cows with LDA and 89,5 % in cows with RDA. The oxygen saturation in cows with LDA did not correlate to the gas pressure nor to the gas volume of the displaced abomasum. In cows with RDA, the oxygen saturation correlated negatively to the gas volume ($r_s = -0,16$) and to the gas pressure ($r_s = -0,15$).

The average intraluminal pressure and the abomasal gas volume in cows with LDA ($6,04 \pm 2,16$ mmHg respectively $7,98 \pm 2,04$ l) was significantly lower than in cows with RDA ($12,86 \pm 5,60$ mmHg respectively $11,53 \pm 3,86$ l). The weak correlation between gas pressure and gas volume can be a result of other factors which influence the intraabdominal pressure and volume, like ruminal content or tension of the abdominal wall. Factors causing the relatively weak correlation between gas pressure and volume on one hand and the oxygen saturation on the other hand might be the unknown time lapse (in most cases) between the beginning of the abomasal displacement and the admission into the clinic, the imprecise degree of disturbance in the motility and the unknown amount of fluid in the abomasum.

The application of pulse oximetry to the gastrointestinal tract in cattle during laparotomy is feasible and requires a short amount of time. In the cows in this study, the measured oxygen saturation indicated that the perfusion of the displaced abomasum was altered in LDA as well as in RDA. Probable

reasons for this disturbance are the impact of pressure caused by the content of gas and fluid to the abomasal wall, the compression of the blood vessels due to the distension of the abomasal wall and the influence of the displacement or torsion of the abomasum itself on the the vessels in the omentum. Severe disturbances in perfusion have to be expected in cases of right abomasal displacement where severe torsions of the abomasum are present. This technique can be useful to establish a prognosis and metaphylactic therapeutic efforts to prevent reperfusion injuries, paralytic postoperative ileus, and abomasal atony.

ANTIBIOTIC SUSCEPTIBILITY AND RESISTANCE OF *STAPHYLOCOCCUS CHROMOGENES* FROM BOVINE MASTITIS

An unselected series of seventy-six strains isolated from subclinical mastitis from forty-four dairy herds in Flanders, Belgium, tentatively identified as *Staphylococcus chromogenes* was examined for confirmation of identification and antibiotic susceptibility patterns.

The presumptive identification was only based upon complete absence of hemolysis and a typically weakly positive DNase test, usually with yellow pigmentation. A confirmatory identification was performed by tRNA intergenic spacer PCR as described by Maes et al. (1997, J. Clin. Microbiol. 35, 2477-2481). Antibiotic resistance profiles to several antibiotics were determined as MIC's (Minimal Inhibitory Concentrations) using agar plate dilution on Mueller-Hinton II medium (BBL) according to NCCLS guidelines. The presence of β -lactamase was tested by visual inspection of the margins of penicillin disk diffusion zones (positive when heaped up with fully grown colonies), and the nitrocefin test (Oxoid). *mecA* Gene determination with PCR was carried out only on penicillin-resistant strains in order to detect methicillin-type resistance (resistance to β -lactamase-resistant penicillins and cephalosporins).

Confirmation of identification by PCR resulted in sixty-two strains of *S. chromogenes*, three strains of *Staphylococcus sciuri*, one remarkable *Staphylococcus aureus* (described below), and ten unidentified strains. The antibiotic resistance profiles of the *S. chromogenes* are described as MIC₉₀ and MIC₅₀ and given in Table 1.

Table 1. Susceptibility of *S. chromogenes* from bovine mastitis (n = 62).

	Peni G	Cloxa	Tetra	Tylo	Ery	Linco	Genta	Neo	Enro
MIC ₉₀	0.12	0.50	0.25	1.00	0.25	1.00	≤0.06	0.25	0.12
MIC ₅₀	≤0.06	0.25	0.25	0.50	0.25	0.50	≤0.06	0.25	0.12

Twenty-four strains of *S. chromogenes* were β-lactamase-positive and the presence of β-lactamase was associated with pigmentation (Fisher Exact test: P = 0.002). Of the fifty-one yellow-pigmented strains only fifteen were β-lactamase positive, while nine out of eleven white colonies were β-lactamase positive. The results of visual inspection of the margins of penicillin inhibition zones completely corresponded to those of nitrocefin tests. The *mecA* gene, indicating methicilline resistance, was found in two strains. One of these strains was not pigmented, DNase negative, non-hemolytic, tube coagulase-negative, clumping factor-negative, lipase-negative, lecithinase-negative and novobiocin-resistant and proved to be a highly atypical *S. aureus*. This was confirmed by tRNA intergenic spacer PCR, *femB* gene determination, and acriflavine (8 µg/ml) resistance. A second strain was identified as *S. sciuri*.

The dilution method, with the NCCLS recommended low number of cells (10⁵), is not suitable to determine susceptibility and resistance to penicillins and cephalosporins in staphylococci. In comparison with reports of the susceptibility patterns of *S. aureus*, *S. chromogenes* appeared to have a similar antibiotic resistance profile, though the resistance rates may be somewhat lower.

PREVALENCE OF TEAT APEX COLONIZATIONS BY *S. CHROMOGENES* IN YOUNG AND PRIMIGRAVID DAIRY HEIFERS

Little attention has been paid to intramammary infections (IMI) in dairy heifers as their non-lactating udders have traditionally been considered as uninfected. However, high prevalences of IMI in non-lactating and freshly calved heifers, mainly caused by Non-*aureus* staphylococci (NAS), were reported (1). Prevalence of teat apex and teat skin colonizations is also high. They are mainly caused by the same species (3). The aim of this study was to examine the prevalence of teat apex colonization with *Staphylococcus chromogenes*, one of the most prevalent NAS, in young and primigravid dairy heifers, and the effect of age on this prevalence.

In a cross-sectional study, teat ends (n=492) were sampled from in total 123 heifers, on eight dairy herds. The age of the heifers varied from 8 to 34 months. The heifers were immobilized and the teat apices were cleansed with a sterile cloth, sampled with a swab (Cultiplast®) and put on to a transport medium. All swabs were streaked on a blood agar plate and incubated aerobically at 37°C. Bac-

terial growth was recorded after 24 and 48 hours of incubation. Identification was performed as described by Devriese et al. (2). A teat apex was classified as infected with *S. chromogenes* when at least 8 colony forming units were isolated. Prevalences were calculated as the percentage of heifers with at least one infected teat apex and as the percentage of infected teat apices. The mean number of infected teat apices per heifer was also calculated. Logistic regression was used to analyze the effect of age of the heifers on prevalence of *S. chromogenes*. Odds Ratio's (OR) per age group, using the youngest age group as reference, were calculated (95% Confidence Intervals-CI)(SPSS 10.0). The mean age of the heifers at the moment of sampling was 18.7 months. Overall, 20.3% of the heifers had *S. chromogenes* infected teat apices, while 9.7% of all teat apices were infected with *S. chromogenes*. There was a significant influence of age class on the prevalence of infected heifers ($P < 0.05$). Prevalences of infected heifers (with OR), prevalences of infected teat apices per age class, and mean number of infected teat apices per heifer are presented in Table 1.

Table 1: Prevalences of *S. chromogenes* infected heifers and *S. chromogenes* infected teat apices per age class and mean number of infected teat apices per heifer.

Age class	N (heifers)	Prevalence (% of heifers)	OR (95% CI)	Prevalence (% of apices)	Mean infected number of infected teat apices per heifer
8 - 12 months	22	9,1%		4,5%	2
>12 - 20 months	52	7,7%	0,8 (0,1- 4,9)	3,4%	1,75
>20 - 28 months	37	35,1%	5,4 (1,1 - 26,9)	16,2%	1,85
>28 - 34 months	12	50,0%	10,0 (1,6 - 63,1)	27,1%	2,16

This study shows that heifers older than 20 months of age run a higher risk of having *S. chromogenes* infected teat apices than younger ones. Further, longitudinal studies will reveal whether IMI post partum can be predicted by *S. chromogenes* teat apex colonizations and whether there is a quantitative effect. If an association exists, possible risk factors for teat apex colonization can be identified and can be used to reduce the high prevalence of IMI in freshly calved dairy heifers.
